Computing · Benchmarks · Opportunistic Usage

1 Introduction

28

29

Particle physics experiments at the Large Hadron Collider (LHC) need a great quantity of computing resources for data processing, simulation, and analysis. This demand will be growing with the upcoming High-Luminosity upgrade of the LHC [1]. To help fulfill this requirement, High Performance Computing (HPC) resources provided by research institutions can be useful supplements to the existing World-wide LHC Computing Grid (WLCG) [2] resources allocated by the collaborations.

This paper presents the concepts and implementation of providing a HPC resource, the shared research cluster NEMO [3] at the University of Freiburg, to AT-LAS and CMS users accessing external clusters connected to the WLCG with the purpose of accommodating data production as well as data analysis on the HPC host system. The HPC cluster NEMO at the University of Freiburg is deploying an OpenStack [4] instance to handle the virtual machines. The challenge is in provisioning, setup, scheduling, and decommissioning the virtual research environments (VRE) dynamically and according to demand. For this purpose, the schedulers on NEMO and on the external resources are connected through the Roced service [5].

A VRE in the context of this paper is a complete software stack as it would be installed on a compute cluster fitted to the demands of ATLAS or CMS workloads.

2 Virtualization infrastructure

Hardware virtualization has become mainstream tech-₉₇
nology over the last decade as it allows to host more ₉₈
than one operating system on a single server and to ₉₉
strictly separate users of software environments. Hard-₁₀₀
ware and software stacks are decoupled and therefore
complete software environment can be migrated across
hardware boundaries. While widespread in computer¹⁰¹
center operation this technique is rarely applied in HPC.

The computer center at the University of Freiburg pro-¹⁰⁶ vides medium scaled research infrastructures like cloud,¹⁰⁷ storage, and especially HPC services adapted to the¹⁰⁸ needs of various scientific communities. Significant stan-¹⁰⁹ dardization in hardware and software is necessary for¹¹⁰ the operation of compute systems comprised of more¹¹¹ than 1000 individual nodes combined with a small group¹¹² of administrators.

The level of granularity of the software stack pro-114 vided is not fine enough to directly support the require-115 ments of world-wide efforts like the ATLAS or CMS ex-116 periments. Therefore, novel approaches are necessary to 117 ensure optimal use of the system and to open the clus-118 ter to as many different use-cases as possible without 119 increasing the operational effort. Transferring exper-120 tise from the operation of the established local private 121 cloud, the use of OpenStack as a cloud platform has 122 been identified as a suitable solution for NEMO. This 123 approach provides a user defined software deployment 124 in addition to the existing software module system. The 125 resulting challenges range from the automated creation 126 of suitable virtual machines to their on-demand deploy-127 ment and scheduling.

2.2 Research Cluster NEMO

The research cluster NEMO is a cluster for research in₁₃₃ the federal state of Baden-Württemberg in the scien-₁₃₄ tific fields of Elementary Particle Physics, Neuroscience₁₃₅ and Microsystems Engineering. Operation started on₁₃₆ the 1st of August 2016 and consists currently of 900₁₃₇ nodes with 20 physical cores and 128 GiB of RAM each.₁₃₈ Omni-Path [6] spans a high speed low latency network₁₃₉ of 100 Gbit/s between nodes. The parallel storage has₁₄₀ 768 TB of usable capacity and is based on BEEGFS [7].₁₄₁

A pre-requirement to execute a VRE is the efficient₁₄₂ provisioning of data which has to cross institutional₁₄₃ boundaries in the CMS use-case. To transfer the in-₁₄₄ put data into the VRE from the storage system at the₁₄₅

KIT and to store back the results a signficant bandwidth is needed. The NEMO cluster is connected with two 40 Gbit/s links to the main router of the University of Freiburg which itself is linked to the network of scientific institutions in Baden-Württemberg, BelWü, at 100 Gbit/s.

2.3 Separation of software environments

The file system of a VRE is a disk image presented as a single file. From the computer center's perspective this image is a "black box" requiring no involvement or efforts like updates of the operating system or the provisioning of software packages of a certain version. From the researcher's perspective the VRE is an individual virtual node whose operating system, applications and configurations as well as certain hardware-level parameters, e.g. CPU and RAM, can be configured fully autonomously by the researcher within agreed upon limits.

To increase the flexibility in hosted software environments, the standard bare metal operation of NEMO is extended with an installation of OpenStack components [8]. The NEMO cluster uses Adaptive's Workload Manager Moab [10] as a scheduler of compute jobs. OpenStack as well can schedule virtual machines on the same nodes and resources. To avoid conflicts, it is necessary to define the master scheduler which decides the job assignment to the worker nodes. Both Moab and OpenStack are unaware that another scheduler exists within the cluster and there is no API which enables them to communicate with each other. Since the majority of users still use the bare metal HPC cluster, Moab is deployed as the primary scheduler. It allows for detailed job description and offers sophisticated scheduling features like fair-share, priority-based scheduling, detailed time limits, etc. OpenStack's task is to deploy the virtual machines, but Moab will initially start the VRE jobs and the VRE job will instruct OpenStack to start the virtual machine on the reserved resources with the required flavor, i.e. the resource definition in OpenStack.

When a VRE job is submitted to the NEMO cluster, Moab will first calculate the priority and the needed resources of the job and then inserts it into its queue. When the job is in line for execution and the requested resources are available, the job will start a script which then starts the VRE on the selected node within the resource boundaries. During the run-time of the VRE a monitoring script regularly checks if the VRE is still running and terminates the job when the VRE has ended. When the job ends, OpenStack gets a signal to terminate the virtual machine and the VRE job ends

as well. Neither Moab nor OpenStack have access inside 191 the VRE, so they cannot assess if the VRE is actually 192 busy or idle. The software package Roced (described 193 in further detail in Section 4) has been introduced to 194 solve this issue. It is used as a broker between different 195 HPC schedulers, translating resources and monitoring usage inside the virtual machine, as well as starting and stopping VRE images on demand.

The VREs for ATLAS and CMS software environments consist in OpenStack containers in the format of compatible VM images. These images are provided in an automatized way allowing versioning and archiving of the environments captured in the images.

3.1 Packer combined with Puppet

A reasonable approach to generate the image is the open-source tool Packer [11], interfaced to the system configuration framework Puppet [13]. Packer allows to configure an image based on an ISO image file using a likickstart [12] file and flexible script-based configuration. It also provides an interface to Puppet making it particularly convenient if an existing Puppet role is to be used for the images. If the roles are defined according to the hostname of the machine as is conventional in Puppet with Hieradata, the hostname needs to be set tificates requires an initial manual start of a machine with the same hostname to allow handshake signing of the certificate from the Puppet server.

Packer's interface to Puppet allows a fully auto-²¹⁹ mated image generation with up-to-date and version-²²⁰ controlled configuration. At the end of the generation²²¹ run, the image is automatically transferred to the Open-²²² Stack image server.

3.2 Image generation using the Oz toolkit

Another option to employ a fully-automated procedure²²⁸ is to use the Oz toolkit [14]. All requirements and con-²²⁹ figuration options of an image can be specified through²³⁰ a XML template file. The partitioning and installation²³¹ process of the operating system is fully automated, as²³² Oz will use the remote-control capabilities of the local²³³ hypervisor. After the installation of the operating sys-²³⁴ tem, additional libraries and configuration files can be²³⁵ installed. Once the image has been created, it is auto-²³⁶ matically compressed and uploaded to a remote cloud²³⁷

site. This technique allows to build images in a reproducible fashion, as all templated files are version controlled using git. Furthermore, existing template files are easy to adapt to new sites and experiment configurations.

4 Interfacing batch systems and virtual resources using Roced

While HPC systems with support for virtualized research environments and commercial cloud providers offer the necessities to acquire computing and storage capacity by dynamic resource booking, the computing needs of high energy physics research groups additionally require workflow management systems capable of maintaining thousands of batch jobs. Some cloud providers, for example Amazon with AWS Batch [15], provide a service for workflow management, however these offerings are often limited to one specific cloud instance. To dynamically distribute batch jobs to multiple sites and manage machine life-time on specific sites, a combination of a highly-scalabe batch system and a virtual machine scheduler is desirable.

$4.1 \; {\it Roced}$

205

225

226

Many capable batch systems exist today and they can be interfaced to virtualization providers using the cloud meta-scheduler Roced (Responsive On-demand Cloud Enabled Deployment) which has been developed at the KIT since 2010 [5]. Roced is written in a modular fashion in python and the interfaces to batch systems and cloud sites are implemented as so-called *Adapters*. This makes Roced independent of specific user groups or workflows. It provides a scheduling core which collects the current requirement of computing resources and decides if virtual machines need to be started or can be stopped. One or more Requirement Adapters report the current queue status of batch systems to the central scheduling core. Currently, Requirement Adapters are implemented for the Slurm, Torque/Moab, HTCondor and GridEngine batch systems. The Site Adapters allow Roced to start, stop, and monitor virtual machines on multiple cloud sites. Implementations exist for Amazon EC2, OpenStack, OpenNebula and Moab-based virtualization at HPC centers. Special care has been put into the resilience of Roced: it can automatically terminate non-responsive machines and restart virtual machines in case some machines have dropped out. This allows VM setups orchestrated by Roced with thousands of virtual machines and many tens of thousands of jobs to

Integration Adapters Requirement Adapters **ROCED Core** .. integrates booted compute nodes ... supplies information about needed into existing batch server **Broker** compute nodes, e.g. queue size **HTCondor HTCondor** decides which machines to boot or shutdown Torque Torque **Grid Engine Grid Engine SLURM SLURM** Site Adapters .. boot machines on various Cloud Computing sites Hybrid HPC Cluster **Commercial Providers** OpenStack

261

262

263

264

The open-source project HTCondor provides a workload₂₆₈ management system which is highly configurable and₂₆₉ modular [16]. Batch processing workflows can be sub-270 mitted and are then forwarded by HTCondor to idle271 resources. HTCondor maintains a resource pool, which272 worker nodes in a local or remote cluster can join. Once273 HTCondor has verified the authenticity and features of 274 the newly joined machines, computing jobs are auto-275 matically transferred. Special features are available to₂₇₆ connect from within isolated network zones, e.g. via₂₇₇ a Network Address Translation Portal, to the central 78 HTCondor pool. The Connection Brokering (CCB) ser-279 vice [17] is especially valuable to connect virtual ma-280 chines to the central pool. These features and the well-281 known ability of HTCondor to scale to O(100k) of paral-282 lel batch jobs makes HTCondor well suited as a workload₂₈₃ management system for the use cases described in this₂₈₄ paper.

The VRE for CMS contains the HTCondor client₂₈₆ startd. This client is started after the machine has₂₈₇ fully booted and connects to the central HTCondor pool₂₈₈ at KIT via a shared secret. Due to HTCondor's dynamic₂₈₉ design, new machines in the pool will automatically re-₂₉₀ ceive jobs and the transfer of the job configuration and₂₉₁

4.3 Using Slurm as front-end scheduler

Alternatively to the approach described above, the open-source workload managing system Slurm [18] has been interfaced into Roced by the ATLAS group at University of Freiburg. Slurm provides a built-in functionality for the dynamic startup of resources in the Slurm Elastic Computing module [19]. However, this module is based on the assumption of a fixed maximum startup time of the machines. In the considered case, due to the queue in the host system, the start of a resource can be delayed by a significant, varying time period. In addition the transfer of information, such as error states, from one scheduler to the other, and therefore to the user, is very limited. Therefore, Roced has been chosen as the interface between the Moab scheduler on the host system and the Slurm scheduler on the submission side.

The scheduling system is illustrated in Fig. 2. For Slurm, it is necessary that each potential virtual machine is registered in the configuration at the time of start of the Slurm server as well as the client. Slurm configurations also need to be in agreement between server and client. Therefore, a range of hostnames is registered in the configuration in a way that is mapped to potential IP addresses of virtual machines. These virtual machines have a fixed number of CPUs and memory

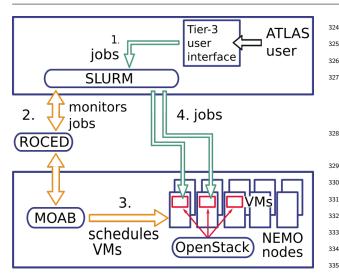

Fig. 2 Implementation of Roced with Slurm on the Tier-3³³⁶ cluster of the WLCG used by ATLAS researchers in Freiburg.³³⁷

assigned and are registered under a certain Slurm partition. When a job is submitted to this partition and no other resource is available, information from the Slurm squeue and sinfo commands is requested and parsed for the required information.

Since the ATLAS Freiburg group comprises three sub-groups, each mapped to a different production account on NEMO, special care is taken to avoid inter-ference of resources used by another account to ensure fair share on NEMO, while nevertheless allowing jobs from one group to occupy otherwise idle resources of another group.

Roced determines the amount of virtual machines³⁵¹ to be started and sends the corresponding VRE job³⁵² submission commands to Moab. After the virtual mac³⁵³ chine has booted, the hostname is set to the IP de³⁵⁴ pendent name which is known to the Slurm configuration. A cron job executes several sanity checks on the³⁵⁵ system. Upon successful execution of these tests, the³⁵⁷ Slurm client running in the VM starts accepting the³⁵⁸ queued jobs. After completion of the jobs and a certain period of receiving no new jobs from the queue,³⁶⁰ the Slurm client in the machine drains itself and the³⁶¹ machine shuts itself down. The IP address as well as³⁶² the corresponding hostname in Slurm are released and³⁶³ can be reused by future VREs.

5 Analysis of performance and usage

The ROCED-based solution described above has been³⁶⁹ implemented and put into production by the research³⁷⁰ groups at the University of Freiburg (Institute of Phys-³⁷¹ ics) and the Karlsruhe Institute of Technology (Insti-³⁷² tute of Experimental Particle Physics). To prove the³⁷³

367

usefulness of this approach statistical analyses of the performance of the virtualized setup both in terms of CPU benchmarks and usage statistics have been conducted.

5.1 Benchmarks

Benchmark tests are performed with the primary goal to measure the performance of the CPU for High Energy Physics applications. Alongside the legacy HEP-SPEC06 (HS06) benchmark [20], the performance of the compute resources is furthermore evaluated with the ATLAS Kit Validation KV [23], a fast benchmark developed to provide real-time information of the WLCG performance and available in the CERN benchmark suite [21]. The primary target is to measure the performance of the CPU for High Energy Physics applications. The KV benchmark is making use of the simulation toolkit GEANT4 [24] to simulate the interactions of single muon events in the detector of the ATLAS experiment and provides as outut the number of events produced per second. It constitutes a realistic workload for High Energy Physics jobs.

To assess the impact of the virtualization, the performance of the identical hardware configuration (20 cores Intel Xeon E5-2630 CPUs) has been determined either deployed via the standard bare metal operation on the NEMO cluster (NEMO bare metal) and on the ATLAS Tier-3 center in Freiburg (ATLAS Tier-3 bare metal), or as virtual machines on the NEMO cluster (NEMO VM). On the ATLAS Tier-3 bare metal and on the virtual machines running on the NEMO cluster, hyper-threading (HT) technology is activated. Both are using Scientific Linux 6 [25] as the operating system. On the cluster NEMO bare metal jobs are restricted to 20 cores by cgroups, since the application mix is broader than on HEP clusters. The operating system is CentOS7 [26]. The scores of the HEP-SPEC06 and KV benchmarks have been determined for these three configurations as a function of the number of cores actually used by the benchmarking processes. This number ranges from 2 to 40 for the ATLAS Tier-3 bare metal and for the NEMO VM, for which HT is enabled, and from 2 to 20 for the NEMO bare metal, for which HT is not implemented. The benchmarks have been run 20 times for each core multiplicity value, and the means and standard deviations of the corresponding distributions have been extracted.

The HEP-SPEC06 and KV results are presented in Figure 3 for the three configurations considered. The

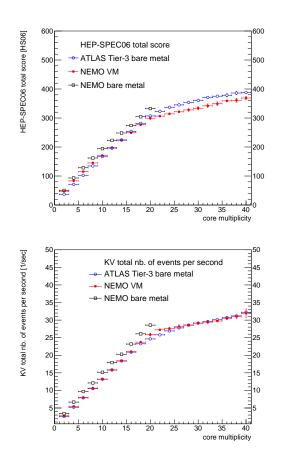

Fig. 3 Total score as a function of the core multiplicity for₃₉₉ the HEP-SPEC06 (top) and KV (bottom) benchmarks for the ATLAS Tier-3 bare metal (blue open circles), the NEMO VMs (red full circles) and the NEMO bare metal (black open⁴⁰¹ squares). The data points represent the average values of the⁴⁰² benchmarks for each core multiplicity, and the vertical bars₄₀₃ show the associated standard deviations.

total scores of the two benchmarks are increasing un-406 til the maximum number of physical cores has been407 reached, and are characterized by a flattening increase408 afterwards. The scores of the virtual machines running409 on the NEMO cluster are only slightly lower than those410 obtained for the NEMO bare metal, and the loss of performance due to the virtualization does not exceed 10%. For the VMs running on the NEMO cluster and411 the ATLAS Tier-3 bare metal, the interplay between the virtualization and the different operating systems412 leads to very similar scores for the two configurations,413 particularly for the KV benchmark, and the loss of per-414 formance is smaller than 10% as well.

5.2 Usage statistics

Fig. 4 shows the utilization of virtual machines which₄₂₀ were orchestrated by Roced depending on the resource₄₂₁ demands of the users of the KIT group. At peak times,₄₂₂

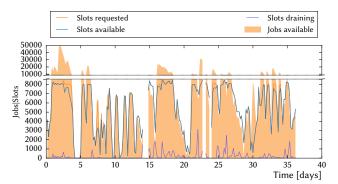

Fig. 4 Utilization of the shared HPC system by booted virtual machines. Up to 9000 virtual cores were in use at peak times. The fluctuations in the utilization reflects the patterns of the submission of jobs by the CMS users at the physics institute in Karlsruhe. The number of draining slots displays the amount of job slots still processing jobs while the rest of the node's slot are already empty.

up to 9000 virtual cores were filled with user jobs, consuming more than a half of the initial 16000 NEMO cores.

The usage of the hybrid cluster model is presented in Fig. 5. The diagram shows the shared usage of NEMO's cluster nodes running either bare-metal or virtualized jobs. The part of the cluster which runs virtualized jobs or VREs changes dynamically from job to job, since the VREs are started by a standard bare-metal job.

At the beginning the cluster was only containing the operating system and some basic development tools. Scientific software was added after the cluster was already in production mode. Since the VRE for the CMS project was already available when the NEMO cluster started, it could already use the whole cluster while other groups still had to migrate from other ressources. This explains the high usage by VREs in the first months of operation. With more and more software being available for bare-metal usage the amount of VRE jobs decreased.

6 Conclusions and Outlook

A novel system for the dynamic, on-demand provisioning of virtual machines to run jobs in a high energy physics context on an external, not dedicated resource as realized at the HPC cluster NEMO at the University of Freiburg has been implemented. An interface between the schedulers of the host system and the external system from which requests are sent is needed to monitor and steer jobs in a scalable way. For this workflow the cloud meta-scheduler Roced has been implemented and deployed for the described use-cases. The approach can be adapted to work with other platforms

The CPU performance and usage of the setup have¹⁸⁴ been analyzed for the job execution environment. The⁴⁸⁵ expected performance loss due to the virtualization has been found to be sufficiently small to be compensated₄₈₈ by the added flexibility and other benefits of this setup.⁴⁸⁹

A possible extension of such a virtualized setup is 490 the provisioning of functionalities for snapshots and mi- 491 gration of jobs. This would facilitate the efficient inte- 493 gration of long-running monolithic jobs into HPC clus- 494 ters

The provided solution extends the available com- $^{496}_{497}$ pute ressources for HEP calculations and could be one $^{498}_{498}$ possibilitly to cope with new data from the upcom- $^{499}_{498}$ ing High-Luminosity upgrade of the LHC. Since HEP⁵⁰⁰ VREs are perfect for backfilling this could be used on $^{501}_{502}$ various cluster ressources.
